(57) **ABSTRACT**

Described herein is a feed forward equalizer that is configured to operate in a normal operational mode and in a test operational mode. The feed forward equalizer has an input port and an output port which are used for the normal operational mode. A test input port and a test output port are provided in the feed forward equalizer, and are used for the test operational mode. Buffers may be provided for matching the impedance of respective ones of the input, output, test input, and test output ports. The feed forward equalizer allows testing during development, and once mounted in an integrated circuit, without interfering with the normal operational mode.

TEST CIRCUITS**CROSS-REFERENCE TO RELATED APPLICATION**

This application claims priority to European Patent Application No. 14161772.0 filed on Mar. 26, 2014, the contents of which are hereby incorporated by reference.

TECHNICAL FIELD

The present disclosure relates to electronic circuits and, more specifically, is related to an improvement for testing electronic circuits.

BACKGROUND

The demand for higher data rates in electronic circuits is permanent. If the data rate of a signal is higher than the bandwidth of a channel used by the signal, the signal integrity can degrade, generating unwanted phenomena like reduced-eye opening, jitter, inter-symbol interference, etc.

Such limitations due to a channel can be overcome with an equalizer located between a signal source and the channel. For example, when a data source sends a signal to an equalizer, the equalizer can introduce predistortion in the signal such that the signal output from a channel located after the equalizer is essentially unchanged with respect to the signal output from the data source. In other words, the equalizer acts as a filter that implements the inverse characteristic of the channel so that the usable frequency range is extended for high data rate signals. At high frequency, the equalizer may be a Feed-Forward Equalizer (FFE), or, more specifically, a travelling-wave type FFE.

A problem may occur when the FFE or its functionality need to be tested, for example, when the gain of variable gain amplifiers of the FFE have to be determined, during the development phase of a product including a FFE, or during the tests following the circuit production. In a practical system, the FFE may be soldered between other circuit components on a Printed Circuit Board (PCB). As such, it may not be possible to test the FFE individually without disconnecting the FFE from the PCB or without inserting test multiplexers that degrade the signal quality, especially at high frequencies.

The FFE may also be integrated in the same integrated circuit as other electronic building blocks, and therefore it becomes difficult to test the FFE individually. Adding test ports next to the conventional input and output ports generally disturbs high-frequency signals because extra circuitry is required on the high speed data path to allow either an internal data signal or an external test signal to be connected to the FFE input and output. This extra circuitry introduces extra power consumption and additional parasitics that degrade the signal quality and bandwidth of the data path.

This problem is acknowledged in the paper "Testable Design for Advanced Serial-Link Transceivers," where Mitchell Lin and Kwang-Ting Cheng describe a design to characterize a Decision-Feedback Equalizer (DFE). This design modifies the conventional DFE topology by using flip-flops.

SUMMARY

The present disclosure may provide a feed forward equalizer that can be tested individually even when associated

2

with other electronic building blocks. The present disclosure may also provide a feed forward equalizer that can be tested using the same components as those used for normal operation.

5 In accordance with one aspect of the present disclosure, there is provided a feed forward equalizer circuit that includes an input port for receiving an input signal, a first line connected to the input port, an output port for providing an output signal, and a second line connected to the output port. In this aspect, the feed forward equalizer circuit also includes a first tap element connected between the first line and the second line at respective line nodes, at least one second tap element connected between the first line and the second at respective line nodes, at least one first delay element connected to the first line between the first tap element and the at least one second tap element, and at least one second delay element connected to the second line between the at least one second tap element and the first tap element. The feed forward equalizer circuit may further comprise a test input port connected to the first line and a test output port connected to the second line. The test input port and the test output port may be respectively connected to first and second line nodes associated with the at least one second tap element.

25 By having a test input port and test output port located in a separate location to the input port and the output port, it is possible to test the elements of the feed forward equalizer circuit irrespective of where it is mounted without interfering with other electronic components of a circuit of which the feed forward equalizer circuit forms a part.

30 In one embodiment, the at least one second tap element comprises a plurality of second tap elements including a first second tap element and a last second tap element, the test input port and test output port being connected respectively to the first and second line nodes associated with the last second tap element.

At least one further test input port and at least one further test output port may be provided, and which are arranged for testing at least one second tap element.

40 In another embodiment, each second tap element is spaced from adjacent second tap elements by respective ones of first and second delay elements.

An input buffer may be associated with the input port and an output buffer may be associated with the output port. In one example, the input and output buffers are impedance matched with respective ones of the input and output ports.

45 Additionally, a test input buffer may be associated with the test input port and a test output buffer may be associated with the test output port. In one example, the test input and test output buffers are impedance matched to respective ones of the test input and test output ports.

In one embodiment, each input buffer and each output buffer includes a current source, each current source being enabled for operation of the respective buffer.

55 In accordance with another aspect of the present disclosure, there is provided an integrated circuit including a feed forward equalizer circuit as described above.

In accordance with a further aspect of the present disclosure, there is provided a method of testing a feed forward equalizer circuit comprising an input port for receiving an input signal; a first line connected to the input port; an output port for providing an output signal; a second line connected to the output port; a first tap element connected between the first line and the second line at respective line nodes; at least one second tap element connected between the first line and the second line at respective line nodes; at least one first delay element connected to the first line between the first tap

element and the at least one second tap element; and at least one second delay element connected to the second line between the at least one second tap element and the first tap; wherein the feed forward equalizer circuit further comprises a test input port connected to the first line and a test output port connected to the second line; and the test input port and the test output port are respectively connected to first and second line nodes associated with the at least one second tap element. In this aspect, the method includes disabling the input port and the output port, introducing a test input signal at the test input port, and measuring a test output signal at the test output port. Further, introducing the test input signal at the test input port may include introducing the test input signal into the feed forward equalizer circuit at the first line node associated with the at least one second tap element during testing.

In one embodiment, the method further includes adjusting parameters of each tap element in accordance with the measured test output signal at the test output port.

In another embodiment, the method further comprises connecting the test output port to a channel and checking the output from the channel for coherency with the input signal introduced into the test input port.

DESCRIPTION OF THE DRAWINGS

For a better understanding of the present disclosure, reference will now be made, by way of example, to the accompanying drawings in which:

FIG. 1 illustrates the signal path in a circuit according to the state-of-art.

FIG. 2a illustrates a feed-forward equalizer according to the state-of-art.

FIG. 2b illustrates a feed-forward equalizer according to an embodiment of the present disclosure.

FIG. 3 illustrates a feed-forward equalizer according to an embodiment of the present disclosure.

FIG. 4 illustrates a buffer circuit used in embodiments of the present disclosure.

FIGS. 5a and 5b respectively illustrate one of two modes of operation of a feed-forward equalizer according to an embodiment of the present disclosure.

FIG. 6 illustrates a feed-forward equalizer and a test channel according to an embodiment of the present disclosure.

FIG. 7 illustrates a block diagram of a feed-forward equalizer according to the state-of-art.

FIG. 8 illustrates a block diagram of a feed-forward equalizer according to an embodiment of the present disclosure.

FIG. 9 illustrates the signal path in another circuit according to the state-of-art.

FIG. 10 illustrates a circuit according to an embodiment of the present disclosure.

DETAILED DESCRIPTION

The present disclosure will be described with respect to particular embodiments and with reference to certain drawings but the disclosure is not limited thereto. The drawings described are only schematic and are non-limiting. In the drawings, the size of some of the elements may be exaggerated and not drawn on scale for illustrative purposes.

In an embodiment of the present disclosure, the electrical signal is a differential electrical signal. However, it will be appreciated that the present disclosure is not limited to differential electrical signals.

The term “high frequency” as used herein is intended to mean a frequency that is higher than one fifth of the transition frequency f_T . Typically, high frequency as used herein refers to frequencies higher than 10 GHz, such as frequencies higher than 40 GHz, for instance.

The present disclosure describes a travelling-wave type feed-forward equalizer (FFE) including test ports such that the FFE characteristics can be fully tested in linear and non-linear regimes.

The operation of a conventional FFE is described with reference to FIG. 1. A data source 101 generates an output signal 102 which forms an input of a FFE 103. The FFE 103 generates an output signal 104 which forms an input for a channel 105. The channel 105 generates a signal 106. The FFE 103 introduces predistortion into the signal 104 such that the output signal 106 from channel 105 located after the FFE 103 is essentially unchanged with respect to the output signal 102 from the data source 101. In one example, the data source 101 is a multiplexer or a serializer and the channel 105 is a metal line on a printed circuit board (PCB).

The signal 102 out of the data source may have a non-return-to-zero (NRZ) modulation scheme and the settings of the FFE 103 may be chosen such that the signal 106 coming out of the channel 105 has also an NRZ modulation scheme. Alternatively, the signal 102 out of the data source may have a non-return-to-zero (NRZ) modulation scheme and the settings of the FFE 103 may be chosen such that the signal 106 coming out of the channel 105 has duobinary modulation scheme.

FIGS. 2a and 2b schematically represent the basic principle of operation of the prior art and the present disclosure, respectively. FIG. 2a shows a conventional FFE 200 with an input port 201 and an output port 202. FIG. 2b shows the FFE 200 with the input port 201, the output port 202, a test input port 203, and a test output port 204.

As shown in FIG. 3, the input port 201 can be connected to the FFE 200 through an input buffer 301. The output port 202 can be connected to the FFE 200 through an output buffer 302. The test input port 203 can be connected to the FFE 200 through a test input buffer 303. The test output port 204 can be connected to the FFE 200 through a test output buffer 304.

In the present example, the input buffer 301 matches the impedance of the element connected to the input of the FFE 200 with the input impedance of the FFE 200. The output buffer 302 matches the impedance of the element connected to the output of the FFE 200 with the output impedance of the FFE 200. The test input buffer 303 matches the impedance of the element connected to the test input of the FFE 200 with the impedance of the test input of FFE 200. The test output buffer 304 matches the impedance of the element connected to the test output of the FFE 200 with the impedance of the test output of FFE 200.

An implementation of a buffer circuit 400 is shown in FIG. 4. A channel or an external circuit (not shown) is connected by an electrical connection 401 to a collector 402 of a NPN bipolar transistor 403 and to a load resistance 404. The other side of the load resistance 404 is connected to a voltage supply 410. An emitter 406 of the NPN bipolar transistor 403 is connected to a current source 407. The other side of the current source 407 is connected to ground 405. A base 408 of the NPN bipolar transistor 403 is connected to the FFE 200. The buffer circuit 400 like that shown in FIG. 4 can be used for the output buffer 302 and/or the test output buffer 304. For the input buffer 301 and the test input buffer 303, the FFE input or test input port is connected to

5

the electrical connection **401** and the base **408** of the NPN bipolar transistor **403** is connected to the data source or an external circuit.

In an embodiment of the present disclosure, the test input port is a pad or a set of pads on the integrated circuit through which electrical contact can be made, for example, by way of test needles or bond wires. In an embodiment of the present disclosure, the test output port is a pad or a set of pads on the integrated circuit through which electrical contact can be made, for example, by way of test needles or bond wires. In an embodiment of the present disclosure, a set of pads comprises three or four pads as usual for high-frequency signals, but it will be appreciated that the present disclosure is not limited to this number and can be any suitable number according to the particular application.

The FFE **200** described in the present disclosure has two modes of operations schematically represented on FIGS. **5a** and **5b**. In a normal mode of operation, shown on FIG. **5a**, the signal **501** enters the FFE **200** by the input port **201** and leaves the FFE **200** by the output port **202**. In this mode of operation, the test input port **203** and test output port **204** are disconnected by means of disconnection elements or circuits **503** and **504**. In an embodiment of the present disclosure where the test input buffer **203** and test output buffer **204** are implemented by the buffer circuit **400** of FIG. **4**, the test input port **203** and test output port **204** are disconnected by switching off the current source **407**. The test input port **203** and test output port **204** do not disturb the signal **501** during the normal mode of operation.

In a test mode of operation, shown on FIG. **5b**, the signal **502** enters the FFE **200** by the test input port **203** and leaves the FFE **200** by the test output port **204**. During the test mode of operation, the input port **201** and output port **202** are disconnected by means of disconnection elements or circuits **505** and **506**. In an embodiment of the present disclosure where the input buffer **201** and output buffer **202** are implemented by the buffer circuit **400** of FIG. **4**, the input port **201** and output port **202** are disconnected by switching off the current source **407**. The input port **201** and output port **202** do not disturb the test signal **502** during the test mode of operation.

During the normal mode of operation, the signal **501** is not disturbed by the test input port **203** or by electrical circuits connected to it, or by the test output port **204** or by electrical circuits connected to it.

During the test mode of operation, the signal **502** is not disturbed by the input port **201** or by electrical circuits connected to it like the data source **101**, or by the output port **202** or by electrical circuits connected to it like the channel **105**.

In an embodiment of the present disclosure, as shown in FIG. **6**, the test output port **204** is electrically connected to a test channel **601**, the test channel **601** being connected to a channel test output port **602**. The test channel **601** may comprise a metal line on a PCB. In an embodiment of the present disclosure, the channel test output port **602** is a pad or a set of pads through which electrical contact can be made, for example, by way of test needles or bond wires.

A state of the art travelling-wave FFE **200** is shown on FIG. **7** and illustrates an implementation of the FFE shown in FIG. **2a**. The travelling-wave FFE **200** includes a first line **710** and a second line **720**. The first line **710** extends between input port **201** and a first termination element **711**. The first line **710** also connects: the input port **201** to the input buffer **301**; the input buffer **301** to a first node **712**; and the first node **712** to a first delay element **715**, the first delay element **715** forming one of a first set of delay elements **716**.

6

The first line **710** connects in series a plurality of delay elements of the first set of delay elements **716**. The first termination element **711** comprises a resistor, for example. The delay elements of the first set of delay elements **716** may be identical transmission lines. However, it will be appreciated that other forms of delay elements can be used.

A plurality of electrical nodes **713** is present on the first line **710** between the input buffer **301** and the first delay element **715** of the first set of delay elements **716**; between the delay elements of the first set of delay elements **716**; and between a last delay element **718** of the first set of delay elements **716** and the first termination element **711**.

The second line **720** extends between output port **202** and a second termination element **721**. The second line **720** also connects: the output port **202** to the output buffer **302**; the output buffer **302** to a first node **722**; and the first node **722** to a first delay element **725**, the first delay element **725** forming one of a second set of delay elements **726**. The second line **720** connects in series a plurality of delay elements of the second set of delay elements **726**. The second termination element **721** is a resistor, for example. The delay elements of the second set of delay elements **726** may be identical transmission lines. However, it will be appreciated that other forms of delay elements can be used.

A plurality of electrical nodes **723** is present on the second line **720** between the output buffer **302** and the first delay element **725** of the second set of delay elements **726**; between the delay elements of the second set of delay elements **726**; and between a last delay element **728** of the second set of delay elements **726** and the second termination element **721**.

A first variable gain amplifier **730** is connected between the first node **712** on the first line **710** and the first node **722** on the second line **720**. A plurality of second variable gain amplifiers **731** is connected between nodes **713** on the first line **710** and nodes **723** on the second line **720**, with the first line **710** connecting the input of the first variable gain amplifier **730** and the inputs of the variable gain amplifiers **731** with a delay element of the first set of delay elements **716** between each input, and the second line **720** connecting the output of the first variable gain amplifier **730** and the outputs of the variable gain amplifiers **731** with a delay element of the second set of delay elements **726** between each output.

In this embodiment, the first and second variable gain amplifiers **730**, **731** form tap elements which are connectable within the FFE in accordance with the signal to be equalized.

In an embodiment of the present disclosure, the FFE includes only two variable gain amplifiers (one first variable gain amplifier **730** and one second variable gain amplifier **731**) with only one delay element **715** in the first line **710** and only one delay element **725** in the second line **720** between the two amplifiers.

Additionally, it is not necessary that each of the delay elements implements an identical delay, and each delay element may implement a different delay to other delay elements. However, by having identical delays, a symmetrical FFE is obtained, for example, if the first delay element **715** on the first line **710** has the same delay as the last delay element **718** on the first line **710**, etc.

The i^{th} delay element of the first set of delay elements **716** creates a time delay $D_{1,i}$ between the input signals of two neighbouring variable gain amplifiers **730** or **731**. The i^{th} delay element of the second set of delay elements **726** creates a time delay $D_{2,i}$ between the output signals of two neighbouring variable gain amplifiers **730** or **731**.

If the signal passing through the first node **712** on the first line **710** is $X(t)$ at the time t , the signal passing through the first node **722** on the second line **720** at the time t is

$$Y(t) = \sum_{i=0}^n \{A_i X[t - \sum_{j=0}^i (D_{1,j} + D_{2,j})]\} \quad (\text{Equation 1})$$

In Equation 1, A_0 is the gain of the variable gain amplifier **730**, A_i (with $i \geq 1$) is the gain of the i^{th} variable gain amplifier **731**, and n corresponds to the number of delay elements in each set of delay elements **713**, **723** and to the number of variable gain amplifiers **731**. $D_{1,n}$ and $D_{2,n}$ thus correspond to respective ones of the delays of the last delay elements **718**, **728**, and A_n corresponds to the gain of the last variable gain amplifier connected at nodes **714** and **724**.

The FFE could be used in normal mode with the test input port instead of the input port and the test output port instead of the output port because it is symmetrical. The difference between the test input port and the input port is in the elements outside the FFE and connected to the FFE. Similarly, the difference between the test output port and the output port is in the elements outside the FFE and connected to the FFE. However, this symmetry may only be obtained in the case where the delay elements are symmetrical, with the first delay element **715** on the first line **710** giving the same delay as the last delay element **718** on the first line **710**, etc.

An embodiment of the present disclosure can be described using FIG. 8. Identical elements in FIGS. 7 and 8 are numbered the same and will not be described again in detail when describing FIG. 8. Compared to the state of the art FFE shown on FIG. 7, the first termination element **711** is replaced by the test input buffer **303** and the test input port **203**, and the second termination element **721** is replaced by the test output buffer **304** and the test output port **204**.

The last variable gain amplifier of the normal mode of operation becomes the first variable gain amplifier of the test mode of operation. In general, in a FFE comprising M variable gain amplifiers, the $(M+1-i)^{\text{th}}$ variable gain amplifier of the normal mode of operation becomes the i^{th} variable gain amplifier of the test mode of operation. In an embodiment of the present disclosure, the value of the gain determined for the $(M+1-i)^{\text{th}}$ variable gain amplifier in the test mode of operation is later used for the gain of the i^{th} variable gain amplifier during normal mode of operation.

If the FFE **103** of FIG. 1 is replaced by two equalizers in parallel, as shown on FIG. 9, the settings of the equalizers can be chosen such that the signal **106** coming out of the channel **105** has a 4-level phase-amplitude modulation scheme (PAM-4). In FIG. 9, the data source **101** generates a first signal **1001** and a second signal **1003** as outputs. The first signal **1001** is an input to a first FFE **1002**. The second signal **1003** is an input to a second FFE **1004**. The first FFE **1002** generates as output a signal **1005**. The second FFE **1004** generates as output a signal **1006**. The signals **1005** and **1006** are inputs of an adder **1007**. The adder **1007** generates as output a signal **1008**. The signal **1008** is an input in the channel **105**.

In an embodiment of the present disclosure, the first signal **1001** is the Most Significant Bit of an NRZ. The second signal **1003** is the Least Significant Bit of an NRZ. The predistortion created by the first FFE **1002** and the second FFE **1004** is such that the signal **106** coming out of the channel **105** has a PAM-4 modulation scheme.

In an embodiment of the disclosure, if the predistortion is created by several FFEs, as in the case of FIG. 9, each of the FFEs has a test input port and a test output port. For example, on FIG. 10, the first FFE **1002** has a test input port **1101** and a test output port **1102** and the second FFE **1004** has a test input port **1103** and a test output port **1104**.

Although the present disclosure has been described with reference to specific embodiments, it will be appreciated that other embodiments are also possible when implementing a test circuit for FFE.

The invention claimed is:

1. A feed forward equalizer circuit comprising:
 - an input port for receiving an input signal;
 - a first line connected to the input port;
 - an output port for providing an output signal;
 - a second line connected to the output port;
 - a first tap element connected between the first line and the second line at respective line nodes;
 - at least one second tap element connected between the first line and the second line at respective line nodes;
 - at least one first delay element connected to the first line between the first tap element and the at least one second tap element;
 - at least one second delay element connected to the second line between the at least one second tap element and the first tap element;
 - a test input port connected to the first line and a test output port connected to the second line, and wherein the test input port and the test output port are respectively connected to first and second line nodes associated with the at least one second tap element.
2. The feed forward equalizer circuit according to claim 1, wherein the at least one second tap element comprises a plurality of second tap elements including a first second tap element and a last second tap element, the test input port and test output port being connected respectively to the first and second line nodes associated with the last second tap element.
3. The feed forward equalizer circuit according to claim 2, wherein the test input port includes a first set of pads through which electrical contact can be made, and wherein the test output port includes a second set of pads through which electrical contact can be made.
4. The feed forward equalizer circuit according to claim 1, wherein each second tap element is spaced from adjacent second tap elements by respective ones of first and second delay elements.
5. The feed forward equalizer circuit according to claim 1, further comprising an input buffer associated with the input port, and an output buffer associated with the output port.
6. The feed forward equalizer circuit according to claim 5, wherein the input buffer and the output buffer are impedance matched to the input port and the output port, respectively.
7. The feed forward equalizer circuit according to claim 5, further comprising a test input buffer associated with the test input port, and a test output buffer associated with the test output port.
8. The feed forward equalizer circuit according to claim 7, wherein the test input buffer and the test output buffer are impedance matched to the test input port and the test output port, respectively.
9. The feed forward equalizer circuit according to claim 8, wherein each input buffer and each output buffer includes a current source, each current source being enabled for operation of the respective buffer.
10. An integrated circuit including a feed forward equalizer circuit, wherein the feed forward equalizer circuit comprises:
 - an input port for receiving an input signal;
 - a first line connected to the input port;
 - an output port for providing an output signal;
 - a second line connected to the output port;

9

a first tap element connected between the first line and the second line at respective line nodes;
 at least one second tap element connected between the first line and the second line at respective line nodes;
 at least one first delay element connected to the first line between the first tap element and the at least one second tap element;
 at least one second delay element connected to the second line between the at least one second tap element and the first tap element;
 a test input port connected to the first line and a test output port connected to the second line, and wherein the test input port and the test output port are respectively connected to first and second line nodes associated with the at least one second tap element.

11. A method of testing a feed forward equalizer circuit comprising an input port for receiving an input signal; a first line connected to the input port; an output port for providing an output signal; a second line connected to the output port; a first tap element connected between the first line and the second line at respective line nodes; at least one second tap element connected between the first line and the second line at respective line nodes; at least one first delay element connected to the first line between the first tap element and

10

the at least one second tap element; and at least one second delay element connected to the second line between the at least one second tap element and the first tap element; wherein the feed forward equalizer circuit further comprises a test input port connected to the first line and a test output port connected to the second line; and the test input port and the test output port are respectively connected to first and second line nodes associated with the at least one second tap element, the method comprising:

disabling the input port and the output port;
 introducing a test input signal at the test input port into the feed forward equalizer circuit at the first line node associated with the at least one second tap element during testing; and
 measuring a test output signal at the test output port.

12. The method according to claim **11**, further comprising adjusting parameters of each tap element in accordance with the measured test output signal at the test output port.

13. The method according to claim **12**, further comprising connecting the test output port to a channel and checking the output from the channel for coherency with the input signal introduced into the test input port.
